EXECUTIVE SUMMARY

Results of some recent juvenile salmonid spillway passage investigations at The Dalles Dam on the lower Columbia River have shown lower than desired ($\geq 98\%$) survival estimates, particularly for southern spillbays, under certain hydraulic conditions. The contributory factors deemed responsible for lower survival and high injury rates were potential fish collisions with downstream solid objects (e.g., dentates, rock outcrops), long exposure-duration to stilling basin turbulence, shallower “water cushion” depths (particularly at a low tailwater elevation), and lateral flow transporting entrained fish from the south to the north side of the stilling basin. The lower survival and high fish injury rates raised concerns for safe passage at the site and stimulated a search for potential solutions. The present investigation was a two part experiment at Spillbays 2 and 4; the first experiment was conducted in fall 2002 (22 October to 3 November) to evaluate the effects of differential spill volumes at low tailwater elevation. The second experiment, conducted from 20 May to 10 June 2003 at high tailwater elevation, was designed to test the hypothesis whether post-passage distribution and survival of entrained fish would be enhanced with higher spill volumes (e.g., 9 to 21 kcfs), spill from an adjacent spillbay acting as a “water barrier wall” simulating a training wall (to minimize lateral transport of fish), and deeper water “cushion” depths.

The investigation utilized the HI-Z balloon tag-recapture technique to (1) estimate direct passage survival of hatchery reared chinook salmon smolts, *Oncorhynchus tshawytscha*, within $\leq \pm 3\%$, 90% of the time under low (fall) and high (spring) tailwater conditions; fish were released at multiple locations within each spillbay, and (2) better understand causal mechanisms for injury/mortality to assist in future spillway modifications for safer fish passage and how injury potential can be minimized.

The various treatments in the two experiments were not directly comparable with respect to spill pattern, spill volume, or fish release locations. The fall experiment consisted of releasing fish (average total fish length 175 mm) at two depths (shallow, 8 ft above the ogee and deep, 4 ft above the ogee) at two spill volumes (4.5 and 12 kcfs) within Spillbays 2 and 4 (eight treatments). The spring experiment (16 treatments, average total fish length 148 mm) consisted of releasing fish at three (Spillbay 4) to four (Spillbay 2) spill volumes of 9, 12, 18, or 21 kcfs. Release depths were 10 ft (deep) and 15 ft (shallow) above the ogee; lateral release locations were mid-spillbay or off-center (Spillbay 2 only). The lateral releases were made to test the assumption (based on results of computational fluid dynamic model) that mid-spillbay released fish were more likely to pass between the baffle blocks downstream of spillbays than off-center releases; fish released off-center within a spillbay were presumed to have a higher probability of collision with baffle blocks resulting in higher injury/mortality rates.

Water temperatures ranged from 9.0 to 14.5°C (48.2 to 58.1°F) in the fall and 12.5 to 15.5°C (54.5 to 60.0°F) in the spring.

Recapture rates (physical retrieval of alive and dead fish) were high for both fall and spring releases (94-100% in the fall and 96-99% in the spring). Little tag dislodgment (fish assumed dead in calculations) occurred in either group, about 0.4% of all treatment fish in each experiment had dislodged tags. Predation rates also were low in spring; ($\leq 1\%$) for any treatment or control group. However, a higher predation rate (up to 4%) was observed for Spillbay 2 deep released fish in the fall; these occurred in the first two trials at water temperatures of $\geq 14.0^\circ\text{C}$ ($\geq 57.2^\circ\text{F}$).

In the fall, higher survival correlated with higher spill volume and total spill volume at both Spillbays 2 and 4. Survival probability was virtually an ideal 1.0 (0.995 to 1.00) for fish released deep at 12 kcfs spill volume and total spill of 72 kcfs; at lower spill volume (4.5 kcfs and total spill of 33 kcfs) fish survival probability at the deep location ranged from 0.925 to 0.965. Survival also differed

between release depths between spillbays but the trend was not consistent. Survival was lower (0.969) for shallow fish released in Spillbay 2 probability than for those released in Spillbay 4 (0.986) at spill volume of 12 kcfs; within Spillbay 2 survival was higher (1.0) for shallow released fish than those released at deeper depth (0.967, total spill volume 12 kcfs). However, survival was similar (0.986 to 0.995) for fish released at two depths within Spillbay 4 at 12 kcfs and total spill volume 72 kcfs, the only condition tested.

In the spring 2003, survival probabilities differed between spill volumes and fish release locations. At Spillbay 2 where four spill volumes (9, 12, 18, and 21 kcfs) were tested, survival was maximized (0.978 to 1.0) at 18 kcfs with generally lower survival at 9 kcfs (0.931 to 0.975) and 21 kcfs (0.931 to 0.982). At Spillbay 4, survival was maximized (0.944) at 12 kcfs. With respect to individual fish release locations, confounding patterns were observed. Fish released through the deep pipe located off-center in Spillbay 2 had substantially lower survival (0.931) at both 9 and 21 kcfs than for those released at the mid-bay location (0.972 to 0.982); the difference at 9 kcfs was significant ($P<0.10$, one-tailed Z-test). However, a reverse situation was observed for fish released at the shallow location at 21 kcfs; survival was higher (0.982) for off-center released fish than for mid-spillbay released fish (0.951). All Spillbay 4 releases were made at mid-spillbay. Therefore, no off-center data are available from Spillbay 4 in the present study.

Both fall and spring clean fish probabilities (fish without any passage related maladies) generally followed the trends observed for survival estimates. In both seasons, the highest clean fish estimated probabilities were associated with 12 kcfs (fall) or 12 and 18 kcfs (spring) spill volumes. The lowest fall clean fish estimate (0.91) occurred for Spillbay 2 deep fish releases at 12 kcfs. Shallow fish releases in the same spillbay, however, had a 0.98 clean fish estimate at 12 kcfs. The lowest spring clean fish estimates (0.83 to 0.92) were also observed in Spillbay 2 but at 9 and 21 kcfs spill volumes. The fall clean fish estimate for Spillbay 2 at 4.5 kcfs discharge (0.91), although not the lowest, was significantly ($P<0.10$) lower than the Spillbay 4 estimate (0.99). In spring tests, the lowest clean fish estimate (0.83) also occurred in Spillbay 2 but at the highest (21 kcfs) spill volume tested and at the deep, off-center release. This estimate was significantly ($P<0.10$) lower than all other spring estimates except for the 21 kcfs, deep, mid-bay releases. Sensor fish data, bead and computational fluid dynamics (CFD) model studies by Pacific Northwest National Laboratory (PNNL) corroborate the clean fish estimates with the worst hydraulic conditions found at Spillbay 2, deep, off-center releases.

In general, the study succeeded to a large extent in identifying spill patterns and spill volumes that are conducive to enhanced fish passage survival. A spill volume of 12 to 18 kcfs accompanied with some spill from other spillbays provided survival >0.97 ; of the nine estimates only one (0.973 for shallow mid-spillbay released fish at 18 kcfs in Spillbay 4) was slightly less than the desirable survival of ≥ 0.98 . In general, fish released off-center of the spillbay suffered higher mortality/injury than those released in mid-spillbay and appeared to be more prone to collide with downstream concrete baffles.

Eye damage and/or head and body bruises were generally the most prevalent visible injury types in both fall and spring tests. Operculum damage was the next most prevalent visible injury among all test groups followed by internal injury. Shear forces are believed to be the cause of most eye and operculum damage observed on treatment fish. Lacerations and bruises are attributed to contact with spillbay or stilling basin structures. The highest incidence of contact injuries (7%) occurred at the deep/off-center release location in Spillbay 2 with 21 kcfs spill volume. Although the range of estimated impact velocities observed was narrow (66 to 69 ft/s) the highest injury rate (11 %) coincided with impact velocity of 69 ft/s; laboratory experiments show that impact velocity higher than 50 ft/s can inflict injuries.

The “water wall barrier” simulated at Spillbay 6 for the 2003 spring experiment appeared to minimize lateral transport of fish. Observations indicated that fish egress (as indexed by retrieval times) improved relative to similar spillway discharge conditions tested in spring 2002. The retrieval times were shorter(*i.e.*, shorter exposure to stilling basin turbulence) in spring 2003 than in 2002.

In summary, the results of the differential spill experiments at The Dalles Dam suggest that spill volumes of 12 and 18 kcfs through a spillbay were most benign. Overall, differences in survival and clean fish estimates between Spillbays 2 (with bounding retaining walls) and 4 (without retaining walls) are deemed high enough to recommend further testing at Spillbay 4, especially at 21 kcfs spill volume, and with off-center releases to compare with mid-spillbay releases. The treatment conditions studied in the present investigation may not be representative of all the spillbays.

1.0 INTRODUCTION

Juvenile salmonids on their seaward journey encounter any or all of the following exit routes at hydro dams: turbines, spillways, and bypasses. There are two inter-related concerns associated with passage through any of these routes for overall survival. One is the proportion of fish utilizing any of these routes during emigration and the other is their subsequent post-passage condition and survival. Spill volumes of varying magnitude and duration is used at most hydro dams on the Columbia River Basin to enhance passage effectiveness and overall survival of juvenile salmonids. However, there are considerable physical and hydraulic differences among dams which may influence spill effectiveness, fish survival, or both. Bell *et al.* (1972) and Heisey *et al.* (2003) have reported survival rates ranging from 83 to 100% in passage through spillways at hydroelectric dams on the Columbia River Basin.

Results of some recent studies at The Dalles Dam on the lower Columbia River indicate that spill effectiveness and fish passage survival vary with spill volume (expressed as a proportion to river flow), duration (continuous, day or nighttime), spillbays, and season (Normandeau Associates *et al.* 1996a, 2003; Dawley *et al.* 1998, 2000a,b). Although fish passage efficiency (FPE) at The Dalles Dam spillway is relatively high, passage survival is unacceptably low ($\leq 98\%$) under certain hydraulic conditions. The contributory factors deemed responsible for lower survival and high injury rates were probable collisions with stilling basin structures (*e.g.*, dentates downstream of the spillbays), long exposure duration to stilling basin turbulence, shallower “water cushion” depths (particularly at low tailwater elevation), and lateral flow transporting entrained fish from the south to the north side of the stilling basin (Normandeau Associates *et al.* 2003).

To further the efforts in finding solutions for improving fish passage conditions at The Dalles Dam spillway, the Corps initiated a series of investigations utilizing physical, hydraulic, and computational fluid dynamics (CFD) models. Preliminary results of these models suggest that an installation of a “training” wall downstream of the spillbays could minimize lateral transport of spilled water in the stilling basin and thus improve fish passage conditions by reducing exposure time to the complex turbulence of the stilling basin. However, this assumption needs to be verified as to whether the proposed structural modifications do indeed minimize injury/mortality (direct effects) of spillway entrained fish. Due to a host of factors, test results from a single spillbay may not be representative of all spillbays, therefore it is desirable to test multiple spillbays (*i.e.* bay with and without retaining walls, deflectors, bottom or top spill). Consequently, in the present study the direct effects of passage through a spillbay with (Spillbay 2) and without a simulated retaining wall (Spillbay 4) were evaluated. Estimation of direct effects has assisted in evaluating the effectiveness of structural modifications on fish condition at hydroelectric dams and the need for testing multiple hydraulic conditions (Normandeau Associates and Skalski 2000a,b, 2001; Normandeau Associates *et al.* 2003; Heisey *et al.* 2003).

The objectives of this study were to estimate the direct effects of passage through Spillbays 2 and 4 at two spill volumes at a low tailwater elevation (October-November 2002) and at four spill volumes at a high tailwater elevation (May-June 2003) on immediate (1 h) and 48 h absolute survival and injury rates of juvenile chinook salmon, *Oncorhynchus tshawytscha*. The resulting survival estimates were to be within $\leq \pm 3\%$, 90% of the time. The high tailwater experiment in May-June 2003 was designed to simulate a training wall barrier by creating a “water wall barrier” with spill from adjacent spillbays. In addition, the effect of the passage location, *i.e.*, deep or shallow releases at mid-spillbay or off-center, was also evaluated. The off-center locations in Spillbay 2 (spring only) were selected to test the model prediction of an increased probability of collisions with stilling basin baffle blocks. Collisions with downstream concrete structures at high velocity (> 50 ft/s) could increase

injury/mortality potential. Another objective was to assist with the release and recapture of balloon tagged autonomous sensor fish packages passed through Spillbays 2 and 4; the sensor packages measure the hydraulic conditions that alive fish encounter in spillbay passage and exiting the stilling basin.

1.1 Project Description

The Dalles Dam is the second dam upriver (river mile 191.5 or rkm 306) on the main stem Columbia River (Figure 1-1). The powerhouse was completed in 1957 and is located between Oregon and Washington. The Dalles Dam consists of a powerhouse, a spillway, and a navigation lock. The configuration of this facility is such that the spillway is perpendicular to the river, while the powerhouse is parallel to the river (Figure 1-1). The spillway has an overall length of 1,370 ft and contains 23 gates, each 50 ft wide. Spill is regulated by bottom opening tainter gates that pass water at a maximum depth of approximately 40 ft below the upstream water surface. Each tainter gate passes approximately 1.5 kcfs for each foot the gate is lifted. The typical station hydraulic head is approximately 80 ft (Figure 1-2).

A single row of 9 ft high by 10 ft wide concrete baffles are located in the stilling basin to dissipate energy (Figures 1-2 and 1-3). Three baffles lie downstream of each spillbay approximately 11 ft below normal tailrace elevation. An end sill, another energy dissipation structure, lies about 45 ft downstream of the baffles. This structure is a 13 ft high continuous vertical wall and lies approximately 7 ft below normal tailrace elevation.

2.0 STUDY DESIGN

The study was designed to evaluate the trends in fish passage survival at two spillbays at different spill volumes. All treatments were not duplicated in the two seasons and thus the between season results are not directly comparable. Although the primary emphasis was to obtain precise estimates of passage survival through each spillbay, fish releases were made at multiple locations within each spillbay (laterally and vertically) to evaluate trends, not to detect statistical differences, *per se*. Consequently, statistical tests to detect differences in survival or clean fish estimates could be made only *a posteriori* to examine the trends and sue the information for future investigations. Fish releases in the fall experiment were made between 22 October and 3 November 2002. The spring experiment was conducted between 20 May and 10 June 2003. In both experiments a common control was paired with two treatment releases. This scheme has proven efficient in earlier studies and minimized the use of scarce resources without sacrificing precision (Mathur *et al.* 1999, 2000).

There are two primary components of effects on fish using any exit route: direct and indirect effects. Direct effects are manifested immediately after passage (*e.g.*, instantaneous fish mortality, injury, loss of equilibrium); indirect effects (*e.g.*, predation, disease, physiological stress) may occur over an extended period or distance after passage. The present study was designed to estimate direct effects of passage by a straightforward approach of introducing a known number of balloon tagged alive fish into each spillbay (treatment), recapturing them immediately after passage, enumerating the alive and dead fish, and then carefully examining the condition of each fish. The latter provides an avenue to assess the probable causal mechanisms for injury/mortality and use the resulting information for potential mitigative measures that improve fish passage conditions. Treatment fish were released at multiple locations within Spillbays 2 and 4 at pre-specified spill volumes of 4.5 and 12 kcfs in fall 2002 and 9, 12, 18, and 21 kcfs in spring 2003 (Tables 2-1 and 2-2). Control fish were released downstream of Spillbay 3. During the fall, total spill ranged from 4.5 to 72 kcfs and river flow was 88 to 188 kcfs. In the spring, spill ranged from 98 to 160 kcfs and river flow was 203 to 386 kcfs. Generally, total spill in the spring was approximately 40% of river flow. Appendix Tables A-1 and A-2 provide hourly hydraulic and physical conditions on fish release dates.

2.1 Source and Maintenance of Specimens

Juvenile chinook salmon smolts were obtained from the Carson National Fish Hatchery, Bingen, Washington. Lots of 500 to 800 fish were transported from the hatchery via truck to the headworks of The Dalles Dam and were held in two tanks with a 200 or 600 gal capacity. The fish transport tank was equipped with a recirculation system and supplemental oxygen supply. The approximate transport time from the hatchery to the study site was 0.5 h. Approximately 24 h prior to tagging 150 fish were transferred to a 200 gal holding tank on the upper spillway deck. All fish holding tanks/pools were supplied continuously with ambient river water and were equipped with degassing units (spring only). Fish were held a minimum of 24 h prior to tagging to alleviate handling stress and to acclimate them to ambient river conditions. Ambient river temperature ranged from 9.0 to 14.5°C (48.2 to 58.1°F) in the fall and 12.4 to 15.5°C (54.5 to 60.0°F) in the spring (Tables 2-3 and 2-4).

Lots of 5 to 10 treatment fish on any given day were netted from the supply tank on the upper spillway deck and transferred to the adjacent tagging site with a water-sanctuary equipped net. Fish displaying abnormal behavior, severe injury, fungal infection, or descaling (>20% per side) were not used. The same fish selection criteria were applied to control groups.

Chinook salmon smolts were larger sized in the fall (mean approximately 175 mm TL) than in the spring (mean approximately 148 mm TL). Figure 2-1 shows the length frequency distribution of the treatment and control fish groups in each season.

2.2 Sample Size Requirements

One of the main considerations of the present study was to release an adequate number of fish such that the resulting survival estimates for each spill volume within a spillbay tested would be within $\leq\pm3\%$, 90% of the time. However, the sample size was not pre-selected to detect differences (*i.e.*, for test of hypothesis) in survival between spillbays or spill volumes though *a posteriori* comparisons were made. The sample size is a function of the recapture rate (P), expected passage survival ($\hat{\tau}$) or mortality ($1 - \hat{\tau}$), survival of control fish (S), and the desired precision (ϵ) at a given probability of significance (α). In general, sample size requirements decrease with an increase in control survival and recapture rates. Only precision (ϵ) and α levels can be strictly controlled by an investigator.

In performing the sample size calculations, we assumed capture data from replicate daily releases could be pooled (*i.e.*, natural variability $\sigma^2_\tau = 0$). We calculated that with the following assumptions: a recapture rate of 0.98, control survival rate (S) of 0.99, and spillbay survival ($\hat{\tau}$) of 0.97, a precision (ϵ) level of $\leq\pm0.03$, 90% of the time may be achievable with releasing 264 fish per treatment (Table 2-5).

Based on the results of several spillbay survival experiments (Normandeau Associates *et al.* 2003) from other sites on the Columbia River Basin, including The Dalles Dam, a sample size of approximately 325 fish (assuming 98% control survival, recapture rate of 98%, and expected passage survival of 97%) per treatment spillbay and spill volume may be sufficient to attain a prespecified precision level (ϵ) of $\leq\pm3\%$, 90% of the time (Table 2-5). Although survival estimates, along with their associated precision (ϵ) levels for fish released through each release pipe were generated, they were used only to examine trends. As stated above, the primary emphasis was to release an adequate number of fish such that the resulting survival estimates of entrained fish through each spillbay at specific spill volumes would be within the prespecified precision (ϵ) criterion.

Appendix Table B-1 provides sample sizes used, spill volume, and estimated survival rates from other sites on the Columbia River Basin.

Past experience has suggested that the sample sizes can be adjusted as a study progresses because the results are available daily. If recapture and control survival rates are higher than initially assumed, sample size can be reduced. Conversely, if the values of these parameters are lower than initially assumed, then sample size must be increased to achieve the pre-specified statistical precision. Indeed, during the fall experiment at the prespecified spill volume of 12 kcfs through Spillbays 2 and 4 and total spill of 72 kcfs, the desired precision (ϵ) of $\leq \pm 3\%$, 90% of the time on survival estimates had been met with a release of 240 fish; initially 320 fish had been allocated. The remaining fish were released to estimate passage survival with only 4.5 or 12 kcfs spill volume through Spillbay 2 (Table 2-3).

2.3 Release Conditions

All treatment fish releases were made in Spillbays 2 and 4. Two (Spillbay 4) to four (Spillbay 2) release pipes (6 in diameter) were installed approximately 10 ft upstream of the tainter gate of each spillbay and secured with guide wires and/or brackets to ensure that they remained at the desired depth, did not rotate, or were not drawn toward the spill gate (Figures 1-2 and 2-2). A four inch diameter flexible hose was threaded inside the steel pipe. The terminus of each treatment release hose was secured inside a 6 in sweep elbow oriented downstream. Control fish for all experiments were released in the tailwater below Spillbay 3 near the end sill (Figures 1-2 and 2-3). The control release hose was secured to the end sill by a steel support beam that positioned the end of the hose 3 to 5 ft above the tailwater and was oriented to discharge the fish and water in the direction of the flow.

Release pipe location depth differed between the fall and spring experiments. Pipes were positioned 4 ft (deep) and 8 ft (shallow) above the ogee in the fall 2002 (Figure 1-2). In spring 2003, they were positioned 10 ft (deep) and 15 ft (shallow) above the ogee. Differences in pipe depth release locations were necessitated by the higher spill volumes, particularly >12 kcfs in the spring, precluding the deeper positioning in the fall. Lateral placement of the pipes were the same for spillbays in the fall with both deep and shallow pipes positioned near mid spillbay. In the spring an additional set of pipes was installed in Spillbay 2, approximately 8.5 ft away from the mid-bay pipes (Figure 2-2). These off-center pipes were installed to evaluate the assumption (based on physical-hydraulic model studies) that fish exiting off-center pipes were more likely to strike the downstream baffle blocks than mid-bay releases (Figure 2-4). The exit velocity of the discharge pipe was generally close to the velocity of the river water approaching the tainter gate opening.

The fall 2002 investigation (eight treatments) was conducted at two spill volumes (4.5 and 12 kcfs) through Spillbay 2 with total spill volumes of 4.5, 12, 33, or 72 kcfs (Table 2-1). The 2003 spring study (16 treatments) was conducted at spill volumes of 9, 12, 18, and 21 kcfs through Spillbay 2 and at spill volumes of 9, 12, and 18 kcfs through Spillbay 4 (Table 2-2 and Figures 2-5 and 2-6). The total spill volume for the four individual spillbay spill volumes of 9, 12, 18, and 21 kcfs were 113, 108, 102, and 98.5 kcfs respectively. These spill volumes were maintained for all tests except 9 kcfs on May 30 and 31 when total spill volume was 7 to 47 kcfs in excess of the above stated spill.

Fall tailwater elevations (75.2 to 78.9 ft) were lower than spring elevations (79.0 to 85.3 ft). Net hydraulic head was higher during the fall test (80.1 to 83.3 ft) than spring (73.5 to 79.6 ft); however, the impact velocity of the discharge jet upon intercepting the tailwater was similar, 65.6 to 68.3 fps in the fall and 63.3 to 69.0 fps in the spring. The impact velocity was calculated by adding the vertical and horizontal vectors of velocity. The vertical component was calculated based on the vertical distance from the center of the jet (one half of the critical depth above the ogee) to the water surface in the tailwater. The horizontal component of velocity used in the calculation was the critical velocity

through the gate opening (Duncan Hay, personal communication). Appendix Tables A-3 and A-4 provide impact velocity estimated for each release condition.

2.4 Tagging and Release

The balloon tagging-recapture technique (Heisey *et al.* 1992) followed that used earlier at The Dalles Dam and other hydroelectric projects on the Columbia River Basin (Normandeau Associates *et al.* 1996a,b,c). Briefly, lots of 5 to 10 fish were randomly removed from holding tanks and taken to the adjacent tagging site using a water sanctuary equipped net. Fish displaying abnormal behavior, severe injury, fungal infection, or descaling (>20% per side) were not used. The same fish selection criteria was applied to both treatment and control groups. Fish selected for tagging were anesthetized in a 0.5% MS 222 solution (<5 min) and equipped with two uninflated balloon tags and a miniature radio tag with the dorsal balloon tag (Heisey *et al.* 1992).

Balloon tags were attached via a stainless steel pin inserted through the musculature beneath the dorsal and adipose fins. A uniquely numbered VI tag (Visual Implant, Northwest Marine Technology, Inc., Shaw Island, Washington) was also be inserted in the postocular tissue for use in tracking 48 h survival of individual recaptured fish. Fish also received a fin clip in the event the VI tag became dislodged. Balloon tagged fish were placed in a covered, 20 gal container continually supplied with ambient river water until fully recovered from anesthesia (generally 30 to 45 min, minimum 20 min). After full recovery from anesthesia, fish were individually placed into the induction system, tags were activated, and the fish was released. Inflation time of the tags was partially regulated by the temperature and amount of water injected into the tags just prior to release.

All treatment and control fish were released through an induction apparatus (Figure 2-3) that consisted of a small holding basin attached to a 4 in diameter flexible hose (Normandeau Associates and Skalski 1999, 2000a; Normandeau Associates *et al.* 1996a,b,c). The release hose was supplied with river water to ensure fish were transported quickly within a continuous flow of water to the desired release point (see Section 2.3). The same induction system and release hoses were used to release the sensor fish. In the fall, 675 and 585 treatment fish were released through Spillbays 2 and 4, respectively with a matching control of 530 fish (Table 2-3). This release scheme proved logically effective and provided some economy and utilized a relatively smaller number of fish without sacrificing precision. In the spring, 1595 and 810 treatment fish were released through Spillbays 2 and 4, respectively with a matching control group of 750 fish (Table 2-4).

2.5 Fish Recapture

Upon passage, fish were tracked and retrieved when buoyed to the surface downstream of the spillbays by one of three or four recapture boat crews. In the fall study, boat crews were not permitted to enter the no boating zone until spill had been stopped and clearance was granted from powerhouse personnel. Boat crews were notified of the radio tag frequency of each fish upon its release. Only crew members trained in fish handling were used to retrieve tagged fish. To minimize crew bias, no crew was specifically assigned to retrieve either control or treatment fish.

Radio signals were received on a 5-element Yagi antenna coupled to an Advanced Telemetry receiver. The radio signal transmission enabled the boat crew(s) to follow the movement of each fish after passage and position the boats downstream for retrieval when the balloon tag buoyed the fish to the surface; the boats were required to remain a safe distance downstream of the turbulent discharge. Active radio tags which failed to surface were tracked for a minimum of 30 minutes and then checked periodically thereafter to ascertain if fish displayed movement patterns typical of emigrating smolts or that of a predator. Recaptured fish were placed into an on-board holding facility, and tags were removed (Heisey *et al.* 1992). Each fish was examined for descaling and injuries and assigned appropriate condition codes, if necessary, per the descriptions presented in Table 2-6. Tagging and

data recording personnel were notified via a two-way radio system of each fish's recovery time and condition.

Each recaptured fish was immediately examined for visible injuries and later a likely causal mechanism was assigned. Limited controlled experiments (Neitzel *et al.* 2000; Pacific Northwest National Laboratory (PNNL) *et al.* 2001) to replicate and correlate injury type and characteristic to a specific causative mechanism provides some indication of the cause of observed injuries in the field. However, some injury symptoms can be manifested by two different sources which may lessen the probability of accurate delineation of a cause and effect relationship (Eicher Associates 1987). Detailed descriptions of all injured fish were recorded. To minimize bias, injuries which were known or suspected to be caused by predators and those attributed to the tag (tearing at tag site) were not included in quantifying spillbay passage-related afflictions.

All fish recaptured alive were transferred in 5 gal pails to an on-shore holding pool for assessment of delayed effects (48 h). Pools were continuously supplied with ambient river water and shielded to prevent potential fish escape and avian predation. Each day's treatment and control fish were held together in the same pool for 48 h.

As a precautionary measure, the Corps secured the services of personnel from the U. S. Department of Agriculture to scare gulls from the tailrace. Past experience has shown that the hazing of gulls minimizes the potential loss of buoyed experimental fish, and thus maintains the use of prespecified sample sizes. However, predation by piscivores (*e.g.*, northern pikeminnow and smallmouth bass) on tagged fish could not be controlled.

2.6 Classification of Recaptured Fish

As in previous similar investigations (Normandeau Associates *et al.* 1996a,b,c, 1997; Normandeau Associates and Skalski 1998, 1999, 2000a,b,c) the immediate post-passage status of an individual recaptured fish and recovery of inflated tags dislodged from fish was classified as alive, dead, inflated tag(s) recovered, unknown, or predation. The following criteria have been established to make these designations: (1) alive--recaptured alive and remaining so for 1 h; (2) alive--fish does not surface but radio signals indicate movement patterns typical of emigrating juveniles; (3) dead--recaptured dead or dead within 1 h of release; (4) dead--only inflated tag(s) without fish are recovered and telemetric tracking, or the manner in which inflated tags surfaced, is not indicative of predation; (5) unknown--no fish or dislodged tags are recaptured, or radio signals are received only briefly, and the subsequent status cannot be ascertained; and (6) predation--fish are either observed being preyed upon, the predator is buoyed to the surface, or subsequent radio telemetric tracking indicates predation (*i.e.*, rapid movements of tagged fish in and out of turbulent waters or sudden appearance of fully inflated tags). Preyed upon fish are assumed dead in the survival calculations. The status of unknown fish was assigned alive or dead proportional to the fish of known status. Appendix Tables C-1 through C-7 provide daily trial summaries and disposition of individual fish.

Mortalities of recaptured fish occurring after 1 h were assigned to 48 h although fish were observed at approximately 12 h intervals. Specimens were examined for descaling and injury, and those that died were necropsied to determine the probable cause of death. Additionally, all specimens alive at 48 h were re-anesthetized and closely examined for injury and descaling. The re-examination of immobilized fish minimizes the need for extensive handling and associated stress upon immediate recapture. The initial examination allows detection of some injuries, such as bleeding and minor bruising that may not be evident after 48 h due to natural healing processes (Normandeau Associates *et al.* 1996a,b,c). Injury and descaling were categorized by type, extent, and area of body.

Fish without any visible injuries that were not actively swimming or swimming erratically at recapture were classified as "loss of equilibrium". This condition has been noted in most past studies

and often disappears within 10 to 15 min after recapture if the fish is not injured (Normandeau Associates *et al.* 1996a,b,c). A malady category was established to include fish with visible injuries, major scale loss (greater than 20% on either side), or loss of equilibrium. Dead fish without any of these symptoms were not included in this category. Fish without maladies were designated “clean fish”.

This clean fish metric was developed to standardize depiction of passage-related injury rate and is based solely on fish physically recaptured and examined. Additionally, the clean fish metric in concert with site-specific hydraulic and physical data may provide comparative insights into safer fish passage conditions.

Injuries were also categorized as minor or major (Appendix C), based on laboratory studies by PNNL *et al.* (2001). These are as follows:

- Minor – Injuries that were visible but not life threatening and tended to heal and disappear over the post-exposure observation period. Small bruises (approximately 0.5 cm in diameter) with minor discoloration (most commonly observed at the dorsal insertion of the operculum) were given a minor injury rating because fish quickly recovered from such injuries with no apparent ill effects.
- Major – Any injury that resulted in prolonged (48 h) loss of equilibrium was life threatening, or persisted throughout the post-exposure observation were rated major. For example, a large bruise (approximately 0.5 cm in diameter), damage to the spinal column, cuts with visible bleeding, injured eyeballs (bulging, hemorrhaged, or missing), gill damage (inverted gill arches severe enough to result in bleeding).

2.7 Survival and Clean Fish Estimation and Data Analysis

Passage survival probabilities for each spillbay were estimated relative to the control fish survival (Heisey *et al.* 2003; Mathur *et al.* 1999). Data from the daily control releases were pooled; chi-square test indicated homogeneity ($P>0.05$) between daily trials. The daily trials for each treatment group were also homogeneous ($P>0.05$) and thus were also pooled. The two treatment conditions (two spillbays) and one control condition were simultaneously analyzed and modeled by joint likelihood (Normandeau Associates *et al.* 2000). A likelihood ratio test was used to determine whether recapture probabilities were similar for alive (P_A) and dead (P_D) fish. The statistic tested the null hypothesis of the simplified model ($H_0:P_A=P_D$) versus the alternative of the generalized model ($H_A:P_A\neq P_D$). Depending upon the outcome of this analysis for the 1 h survival the parameters and their associated standard errors were calculated using that model for the 48 h estimation as well.

Separate chi-square contingency tests (Burnham *et al.* 1987) were performed to detect homogeneity ($P=0.05$) between daily trials of each treatment and control group with respect to the frequency of alive, dead, and unknown fish; the statistical outputs of these tests are given in Appendix D along with other chi-square tests and exact probabilities. Contingency tests allow for checking for homogeneity and suggest subsets of data to be pooled in the final estimates (Burnham *et al.* 1987). If heterogeneity ($P<0.05$) was detected, separate survival estimates (weighted by the inverse of their respective variance) were calculated for each trial and results summarized as weighted average.

The clean fish estimate (CFE) was calculated from only recaptured fish. Fish with injuries attributed solely to predator attack or tag induced (tear at tag insertion site) were not included with those having passage related maladies. CFE probabilities for each spillbay were estimated relative to control fish that were free of any maladies using the likelihood model indicated above for estimating survival probabilities. Only the reduced model ($H_0:P_A=P_D$) results were used because the analysis was based on only recaptured fish free of injuries.

The 90% confidence intervals were calculated using the profile likelihood method (Normandeau Associates *et al.* 1996a,b,c). Differences in fish survival and clean fish estimates between spillbays, spill volumes, or fish release locations were tested, *a posteriori*, by z-statistic. These tests allowed the examination of trends in these metrics and not as hypothesis testing. As indicated earlier, sample sizes for the study were selected to achieve a prespecified precision (ε) level at a given probabilities level. Also, it should be noted that because of the nature of these multiple comparisons the generalized probability level ($P=0.05$) is not deemed exact.

The statistical outputs are provided in Appendix D (output discussed in the report are highlighted). All statistical analyses were performed using the Statistical Analysis System (SAS). Only summarized information is discussed in the main body of the report.

2.8 Autonomous Sensor Fish

Sensor fish, an instrumented package designed to determine exposure histories to turbulence and pressure during passage (PNNL *et al.* 2001) were also equipped with two or three balloon tags and a miniature radio tag and released using the identical induction release hose into the same spillbays as for the alive fish. Sensor fish were also released through the control release hose. A total of 120 and 265 treatment sensor fish were released in fall and spring, respectively. Some 40 and 73 control sensor fish were released during the respective study periods. The results of sensor fish passage will be provided by PNNL in a separate report.

3.0 RESULTS

Because of differences in fish release locations, spill volumes, and objectives between the fall 2002 and spring 2003 tests, results for each season are presented separately below. These differences preclude direct statistical comparisons of survival or clean fish estimates. Also, for the sake of brevity and practicality, only the 48 h survival probabilities established for each treatment condition are discussed within the text; however, statistical outputs in Appendix D contain estimates of both 1 h and 48 h survival probabilities.

3.1 Fall 2002 (October to November)

3.1.1 Recapture Rates

Recapture rates (physical retrieval of both alive and dead fish) were high for all release groups (Table 3-1). For treatment groups they were >95% (range 95 to 100%) and for control groups they exceeded 97% (range 97.7 to 98.9%). Most of the recaptured fish were alive. A relatively high proportion (0.038 to 0.044) of fish was assigned dead primarily for Spillbay 2 at deep releases with spill volumes of 4.5 and 12 kcfs. Many of these fish were assumed preyed upon, particularly in the first two daily trials when the water temperature was $\geq 14^{\circ}\text{C}$ ($\geq 57.2^{\circ}\text{F}$). The proportion of treatment fish assigned dead at Spillbay 4 was 0.017 and 0.024 for controls.

Except for daily trials for one treatment (only 4.5 kcfs spill volume, fish released through the deep pipe), chi-square tests indicated homogeneity ($P>0.05$) between the daily trials within other treatment groups, suggesting the daily trial data could be pooled and released fish experienced similar tailrace conditions. The exception noted occurred primarily due to predation or unknown fish status in the first two trials. Of the total chi-square calculated value of 33.12, about 69% of this value was due to the first two treatment trials. Consequently, the average survival probabilities, weighted by the inverse of the variance, were calculated. Likewise, there was some evidence that all the daily control trials may not have experienced similar tailrace conditions over time. In the first daily control trial on 22 October, 23 of 45 (6.7%) were classified as dead or unknown. This trial contributed about 50% of

the total chi-square value of 22.16. However, the difference in frequency of recapture of alive, dead, and unknowns over time was not significant at P=0.05 (P=0.075).

Likelihood ratio tests indicated no significant difference ($P>0.05$) between the simplified ($H_0: P_A = P_D$) and generalized ($H_A: P_A \neq P_D$) models. Thus, survival probabilities and their associated standard errors using the reduced model are presented.

3.1.2 Retrieval Times

Average retrieval times (the time interval between release through the induction system until the fish was retrieved) for treatment groups ranged from 15.6 to 17.1 min and control groups averaged 14.5 min (Figure 3-1). Average retrieval time at Spillbay 2 (15.6 to 16.4 min) was shorter than at Spillbay 4 (16.5 to 17.1 min). Retrieval times for the 12 kcfs tests were slightly longer than from the 4.5 kcfs tests.

3.1.3 48 h Survival Probabilities

Survival differed between spill volumes, spill patterns, and release locations within a spillbay (Table 3-2 and Figure 3-2). With respect to the effects of spill volume within a spillbay, when only 4.5 kcfs spill occurred, survival was lower (0.925) at Spillbay 2; at only 12 kcfs spill volume, survival was higher (0.967) but due to a small sample size (n=45) this difference was not declared statistically significant ($P>0.10$). Survival (0.965) within Spillbay 4 with 4.5 kcfs and an additional 28.5 kcfs spill from other spillbays, was lower than at 12 kcfs spill volume and an additional spill of 60 kcfs from other spillbays (0.995).

With respect to spill pattern and spillbays, differences were more pronounced within Spillbay 2 than in Spillbay 4 and showed opposing trends depending on the fish release locations (Table 3-2 and Figure 3-2). In Spillbay 2 with 12 kcfs and total spill of 72 kcfs, the shallow released fish had a significantly ($P<0.10$, one-tailed z-statistic=1.592) lower survival (0.969) than the deep released fish (1.00). However, with only 12 kcfs spill volume through Spillbay 2 the shallow released fish had a significantly ($P<0.05$, one-tailed z-statistic=1.685) higher survival (1.00) than deep released fish (0.967). The shallow released fish with 12 kcfs in Spillbay 4 and 72 kcfs total spill showed only a slightly lower survival than the deep released fish (0.986 versus 0.995).

With respect to survival between spillbays at comparable spill volumes and spill patterns (12 kcfs and 72 kcfs total) survival was higher (0.986), though non-significant ($P>0.10$), for shallow released fish in Spillbay 4 than for those (0.969) released at the same depth in Spillbay 2 (Table 3-2 and Figure 3-2). For the same 12 kcfs and 72 kcfs total spill at Spillbays 2 and 4, the survival for the deep released fish was near 1.00 for both.

In summary, overall passage survival through Spillbay 4 appears higher at 12 kcfs with additional spill from other spillbays.

3.1.4 Injury Classification, Rates, and Probable Causal Mechanisms

A high percentage (96.7 and 98.5%) of the treatment fish released through Spillbays 2 and 4 was recaptured and available for examination of injuries. Injury percentages given below are based on the total number of recaptured treatment fish examined, adjusted for injured controls, and not on the total number of fish released (Table 3-3). A complete list of injuries and maladies is presented in Appendix Tables C-3 and C-4.

The spill volumes with or without additional spill through other spillbays did not appear to display a definitive trend relative to injury rates (Table 3-3). Visible injuries (excluding loss of equilibrium and scale loss) related to passage were present on 4.1 and 1.5% of all of the examined treatment fish passed through Spillbays 2 and 4, respectively.

The injury rate for the single 4.5 kcfs test condition at Spillbay 2 was 4.8% and ranged from 0 to 7.4% for the four tests at 12 kcfs. The highest rate was for fish passed via the deep pipe. The injury rate for the single 4.5 kcfs test at Spillbay 4 was 0.8 but higher (1.6 and 3.2%) for the two tests at 12 kcfs. The most benign treatment (0.0% injury rate) was shallow release point at Spillbay 2 with only 12 kcfs; however, this is based on only 45 fish. Spillbay 4 deep release with 4.5 kcfs and a total spill of 33 kcfs was also relatively benign with only 0.8% of 339 fish injured.

Visible injuries observed included eye damage (hemorrhaged or ruptured), opercular damage (scraps and tears), bruises and/or scrapes on the head or body, lacerations on the head and/or body, and internal hemorrhage (Table 3-3). Eye damage (2.1%), bruises/scrapes to the body/head (1.4%), and opercular damage (1.3%) accounted for the majority of the injuries observed for fish that passed Spillbay 2. The test conditions at Spillbay 2 which elicited the highest rate of eye damage (3.2%) was at the 4.5 kcfs spill, deep release; opercular damage (2.3%) and bruises/scrapes (2.8%) were highest at the 12 kcfs spill, deep release (total spill 72 kcfs). Eye damage and opercular damage were the injuries most often observed at Spillbay 4 but at very low rates (0.7 and 0.8%, respectively). Eye damage (1.5%) and bruises/scrapes (1.1%) were highest at Spillbay 4 for the 12 kcfs shallow release. Opercular damage (1.5%) was highest for the 12 kcfs deep release. About 16% of all visibly injured fish died during the delayed assessment period. No single injury type was more likely to be lethal over other types. Another 1.4% of all test fish died without visible injuries.

Shear and physical contact with spillway structures were the probable causes of most injuries. Shear was the probable cause of many eye and opercular injuries (especially tears at the dorsal insertion). Physical contact with spillbay surfaces or tailwater structures in the stilling basin was the probable cause of most scrapes and bruises.

The malady rates (all visibly injured fish, plus fish with scale loss of >20% per side, and/or only loss of equilibrium), adjusted for controls, were similar to the injury rates. The overall malady rates at Spillbays 2 and 4 were 5.5 and 1.6%, respectively (Table 3-4). The specific test condition with the highest malady rate (9.2%) occurred for Spillbay 2 deep released fish at 12 kcfs (72 kcfs total spill). Malady rates were considerably less at Spillbay 4, with a maximum of 2.5% at 12 kcfs for both deep and shallow releases.

3.1.5 Clean Fish Estimates

Estimates of clean fish (*i.e.*, recaptured fish without visible injury, scale loss, or loss of equilibrium), along with their 90% confidence intervals are given in Table 3-5 and Figure 3-3. Spillbay 2 clean fish estimates ranged from 0.906 to 1.00 and Spillbay 4 estimates ranged from 0.974 to 0.991. The clean fish estimates for both spillbays at the 12 kcfs spill volume were similar for 5 of 6 test conditions; the exception was 0.906 at Spillbay 2 deep release (12 kcfs spill and 72 kcfs total spill). The two deep release treatment conditions at 4.5 kcfs, though not directly comparable to total spill volumes, through Spillbays 2 and 4 for fish released through the deep pipe were different. The Spillbay 2 estimate (0.928, 90% CI=0.898 to 0.954) was substantially lower than for fish released in Spillbay 4 (0.991, 90% CI= 0.972 to 1.00). At Spillbay 4, the spill volume of 4.5 kcfs was accompanied with a total spill of 33 kcfs; at Spillbay 2 spill was only 4.5 kcfs. Depth of release appeared to be spillbay specific (Table 3-5). Under the same release conditions in Spillbay 2, the clean fish estimate for deep releases (0.906, 90% CI=0.858 to 0.955) was significantly ($P<0.05$, z-statistic) lower than for the shallow released fish (0.983, 90% CI=0.953 to 1.00).

3.2 Spring 2003 (May to June)

3.2.1 Recapture Rates

Recapture rates (physical retrieval of both alive and dead fish) were high but differed between specific hydraulic conditions (Table 3-6). Recapture rates of treatment groups ranged from 95.8 to 100.0%. Recapture rates in Spillbays 2 and 4 ranged from 95.8 to 100% and 97.5 to 100%, respectively. The lowest recapture rate was for Spillbay 2 fish released deep and off-center at 9 kcfs. Recapture rates of control fish ranged from 98.6 to 100.0%. Although most recaptured fish were alive, a greater proportion of Spillbay 2 fish were dead at recapture or were assigned to the dead category (up to 5.3%) than Spillbay 4 (up to 3.7%) fish (Table 3-6). However, less than 0.5% of all fish were preyed on.

Chi-square tests indicated homogeneity ($P>0.05$) between daily trials within each treatment group, suggesting the daily trial data could be pooled; all the daily treatment trials experienced similar tailrace conditions over time. However, chi-square tests indicated daily control trials were not homogeneous at the $P=0.10$ level but were so at $P=0.05$. Most of the variability (about 68% of the total calculated value of chi-square) arose due to one control trial at 18 kcfs spill volume and 102 kcfs total spill on 22 May 2003. Three of 40 fish (7.5%) were presumed preyed upon; virtually all other fish over all control trials were categorized alive. Likelihood ratio tests indicated no significant difference ($P>0.05$) between the simplified ($H_0:P_A=P_D$) and generalized ($H_A:P_A\neq P_D$) models. Thus, survival probabilities and their associated standard errors using the reduced model are presented. These values are highlighted in Appendix D (statistical outputs).

3.2.2 Retrieval Times

Average retrieval times (the time interval between release through the induction system until the fish was retrieved) for treatment groups ranged from 6.5 to 8.5 min and controls averaged 7.2 min (Figure 3-4). Average retrieval time at Spillbay 2 (6.5 to 7.6 min) was slightly shorter than that at Spillbay 4 (7.1 to 8.5 min). Retrieval times were similar for the four discharge volumes tested in Spillbay 2 (6.5 to 7.6 min) and the three discharge volumes tested in Spillbay 4 (7.1 to 8.5 min). Spring retrieval times were shorter than fall retrieval times primarily because during the spring the spill was not stopped after each group of 10 fish were released, consequently, fish were swept downstream towards recapture boats quicker than in the fall.

3.2.3 48 h Survival Probabilities

As in the fall investigation, survival varied between spill volumes and fish release locations within each spillbay (Table 3-7 and Figure 3-5). At Spillbay 2, where four spill volumes (9, 12, 18, and 21 kcfs) were tested, survival was maximized (0.985 to 1.00) for deep mid-bay and off-center released fish at 12 and 18 kcfs. Similarly, in Spillbay 4 where three spill volumes (9, 12, and 18 kcfs) were tested, survival was higher (0.973 to 0.999) at 12 and 18 kcfs than at 9 kcfs (0.966).

With respect to lateral fish release locations in Spillbay 2 (mid-bay versus off-center) survival was generally lower (3 of 4 tests) for off-center deep released fish than those released at mid-bay; the differences (0.04 to 0.05) were most pronounced at 9 and 21 kcfs at which the lowest survival (0.931) was observed. Survival for fish released off-center deep in Spillbay at 9 kcfs spill volume and total spill of 113 kcfs was significantly higher ($P<0.05$, z-statistic one-tailed test=1.74); also off-center deep released fish had significantly ($P<0.10$, z-statistic one-tailed test=1.54) than for off-center shallow released fish (0.982). However, this was not the case for the shallow mid-bay and shallow off-center released fish in Spillbay 2 (Table 3-7 and Figure 3-5). Survival for shallow off-center released fish at 18 kcfs was slightly lower (0.978) than for mid-bay released fish (0.992). At

21 kcfs, survival (0.982) for off-center released fish was 0.031 higher than for those released at a shallow depth in the mid-bay area.

With respect to vertical fish release locations (shallow or deep) at comparable spill volumes, survival patterns were consistent within each Spillbay (Table 3-7 and Figure 3-5). At Spillbay 2, survival was slightly higher for deep released fish at both 18 and 21 kcfs (deep and shallow 18 kcfs 1.00 and 0.92; deep and shallow 21 kcfs 0.982 and 0.951). The same trend continued at Spillbay 4, where deep released fish had a higher survival (0.997) than shallow (0.973) released fish at 18 kcfs; no other spill volume was tested at both deep and shallow pipes at this spillbay (Table 3-7).

In summary, across all conditions tested, passage survival at both spillbays approached or exceeded the desired 98% at 12 and 18 kcfs spill with additional spill from other spillbays. Poorest survival (0.931) occurred at 9 and 21 kcfs for deep, off-center released fish.

3.2.4 Injury Classification, Rates, and Probable Causal Mechanisms

As stated earlier, injury percentages presented below are based on the total number of treatment fish examined, adjusted for injured controls, and not on the total number of fish released. However, nearly all of the fish released (99.1, 98.5, and 99.2% for Spillbays 2 and 4 and controls, respectively) were recaptured.

The injury rate for all test conditions combined at Spillbays 2 and 4 were 3.4 and 2.8%, respectively (Table 3-8). The spill volumes tested at Spillbay 2 (9, 12, 18, and 21 kcfs) and Spillbay 4 (9, 12, and 18 kcfs) appeared to affect injury rates. Spillbay 2 injury rates tended to be lower at 12 (2.8 to 4.5%) 18 kcfs (0.7 to 4.7%) and higher at 9 (2.1 to 11.0%) and 21 kcfs (3.0 to 11%). Injury rates at Spillbay 4 were highest (4.3%) at the 9 kcfs discharge and similar (1.5 to 2.9%) at 12 and 18 kcfs.

Passage location also tended to affect injury rates (Table 3-8). The highest injury rate at Spillbay 2 (11.0%) was for fish that passed by the deeper pipe that was lined up with a stilling basin baffle block (Table 3-8). Lowest injury rate (0.7%) was obtained at shallow, mid-bay with 18 kcfs. The effect of passage location was mixed at Spillbay 4 where the highest injury rate (4.3%) was at the deep pipe with 9 kcfs spill, but low injury rates (1.5 and 1.9%) also occurred for fish passed via the deep pipe at 12 and 18 kcfs.

Visible injuries observed included eye damage (hemorrhage or ruptured), opercular damage (scratches and tears), bruises and/or scratches to the head or body, lacerations on the head and/or body, and internal hemorrhage. The primary injury types at Spillbay 2 were eye damage (1.6%), bruises/scratches (1.3%), and opercular damage (1.0%). Eye damage (1.8%) and bruises/scratches (0.9%) were the primary injury types observed at Spillbay 4. The test conditions at Spillbay 2 which resulted in the highest incidence of eye damage (4.0%) and bruises/scratches (5.0%) was at the deep off-center release site. Opercular damage (3.1%) was also highest at the 21 kcfs discharge but at the shallow mid-bay release site at 21 kcfs. Eye damage (3.0%) at Spillbay 4 was highest for the 9 kcfs deep and mid-bay releases. Bruises/scratches (2%) and opercular damage (1.0%) at Spillbay 4 were highest for the 18 kcfs shallow mid-bay releases. About 41% of all visibly injured fish died during the delayed assessment period. As with fall injuries, no single injury type was more likely to be lethal. A small number of test fish (0.3%) died with no visible injuries.

As observed in the fall, shear and physical contact with solid objects were the probable causes of most injuries. Shear was the probable cause of many eye and opercular injuries (especially tears at the dorsal insertion). Physical contact with spillbay surfaces or tailwater structures in the stilling basin was the probable cause of most scratches and bruises. The highest incidence of eye damage (4.0%) and scratches and bruises (5.0%) observed for the highest discharge (21 kcfs) deep off-center

releases at Spillbay 2 may have been partially due to higher impact velocities in the vicinity of the baffle blocks.

The malady rates (visible injury plus scale loss and loss of equilibrium) were 5.4 and 3.4% at Spillbays 2 and 4, respectively (Table 3-9). None of the treatment fish incurred scale loss (>20% per side); however, the incidence of loss of equilibrium was 2.0 and 0.6% for the combined treatment test conditions at Spillbays 2 and 4, respectively. The highest incidence of loss of equilibrium (5.9 and 6.9%) occurred for Spillbay 2 fish passed at 21 kcfs through the deep pipe positioned near mid-bay or lined up with a baffle block. The highest malady rate (16.9%) at Spillbay 2 was for 21 kcfs at the deep, off-center release point. The highest malady rate (4.3%) at Spillbay 4 occurred at the 18 kcfs, shallow mid-bay test.

3.2.5 Clean Fish Estimates

Estimates of clean fish (*i.e.*, without visible injury, scale loss, or loss of equilibrium), were based on recaptured fish data provided in Table 3-9. Clean fish estimates along with their 90% confidence intervals are given in Table 3-10 and Figure 3-6.

Spillbay 2 clean fish estimates ranged from 0.852 (21 kcfs, deep, off-center release) to 0.988 (18 kcfs, deep, mid-bay release). Spillbay 4 estimates ranged from 0.957 (18 kcfs, shallow mid-bay release) to 0.982 (12 kcfs, deep, mid-bay release). Six of the 12 clean fish estimates at Spillbay 2 were $\geq 95\%$ while all of the estimates at Spillbay 4 were at this level. The trend of higher survival at 12 and 18 kcfs was also evident for the clean fish estimates (Figures 3-5 and 3-6). The clean fish probabilities for Spillbays 2 and 4 were similar (0.918 to 0.988) for deep mid-bay releases at 9, 12, and 18 kcfs. However, there were significant differences ($P<0.05$) between the mid-bay and off-center releases within Spillbay 2 at 9 and 12 kcfs.

The lowest clean fish rates occurred at 21 kcfs for deep releases in Spillbay 2 (Table 3-10). The off-center (0.852) and mid-bay (0.901) releases at 21 kcfs were significant ($P>0.05$). The off-center shallow and deep releases at 21 kcfs differed significantly from each other ($P<0.05$), but the mid-bay and deep releases did not ($P>0.05$). At the highest test discharge of 21 kcfs, clean fish estimates appear to be influenced more by the depth of release than by off-center or mid-bay release position. The lowest clean fish estimate (0.831) was at deep, off-center; however the highest value at this discharge was at shallow off-center (0.951). The clean fish estimates for both deep and shallow releases at 18 kcfs in Spillbays 2 (0.948 and 0.988) and 4 (0.968 and 0.974) were not statistically different ($P>0.05$).

3.3 Sensor Fish

Preliminary data from the sensor fish passed through Spillbays 2 and 4 indicated that alive fish may have been exposed to more severe hydraulic conditions in Spillbay 2 than in Spillbay 4, particularly at the highest spill volume tested (21 kcfs); more severe conditions were observed at 21 kcfs, and highest incidence of impacting a spillbay structures occurred at 21 kcfs, off-center, deep release. Retention time in the stilling basin (upstream of end sill) was longer for Spillbay 4 than Spillbay 2 sensor fish releases; however the hydraulic forces also appeared to be less severe. A complete analysis of the sensor fish data is to be provided in a report by PNNL.

4.0 DISCUSSION

The primary objectives and assumptions established for the fall 2002 (October to November) and spring 2003 (May to June) investigations were met.. Also, the embedded flexibility in the study design allowed evaluation of two additional spill patterns, though with smaller sample releases, during the fall investigation at Spillbay 2. After the pre-specified precision level (ϵ) of $\leq +3\%$, 90% of the time, on the

survival estimates had been achieved with fewer than the proposed fish allocation, the remaining fish were used to assess the potential effects of spill volumes of 4.5 and 12 kcfs from Spillbay 2; no additional spill from other spillbays occurred during these tests.

Identifying the spill volumes and spill patterns may provide regional fishery managers avenues to enhance survival of downmigrants utilizing the spillway for passage at The Dalles Dam. The present study succeeded to a large extent in identifying some hydraulic conditions that appear safer than others.

The survival estimates generated (eight in the fall, 16 during spring) in the present study indicate that a threshold range of spill volume exists at which survival may be maximized. A spill volume of 12 to 18 kcfs accompanied with some spill from other spillbays can enhance fish survival. Of the eight survival estimates for the fall 2002 experiment four exceeded 0.98 (two at Spillbay 4 and two at Spillbay 2) and occurred at 12 kcfs, particularly accompanied with additional spill from other spillbays (total of 72 kcfs). The lowest estimate (0.93) occurred at Spillbay 2 with only 4.5 kcfs spill volume; the survival was 0.965 at Spillbay 4 at spill volume of 4.5 kcfs with a total spill volume of 33 kcfs. Of the 16 survival estimates generated from the spring 2003 experiment, 9 were ≥ 0.98 ; two were nearly 0.98 (0.975 to 0.978). The three lowest survival estimates (0.930 to 0.951) occurred at 9 and 21 kcfs accompanied with total spill volume of 98.5 to 113 kcfs.

These results are corroborated to a certain extent by a previous study using the identical tag-recapture techniques at The Dalles Dam spillway, though the hydraulic conditions were not identical (Normandeau Associates *et al.* 2003). In the 2002 spring investigation at Spillbay 4 with a spill volume of 7.5 to 10.5 kcfs, the survival of chinook salmon smolts was estimated at 0.97; the total spill volume was 40% of the river flow (Normandeau Associates *et al.* 2003).

The hypothesis that fish released off-center in Spillbay 2 would have a lower survival was partially supported in the spring experiment. Of the six pairs of mid-spillbay and off-center releases, survival was lower for four of the off-center releases. These occurred at 9 and 21 kcfs; one occurred at 21 kcfs for fish released at the shallow mid-bay location. Two of the estimates (0.93) were among the lowest obtained during the study. It is likely that at certain spill patterns and spill volumes there is an increased probability of entrained fish colliding with baffle blocks. The most adverse interaction with a baffle block appeared to occur for fish released at the highest tested spill volume, through the deep off-center pipe at Spillbay 2. The lowest fish survival estimates (0.93) and clean fish estimates (0.83) and highest incidence of visible injury (0.11) and malady (0.17) occurred at this condition. The highest incidence of damaged eye (0.04), abrasion (0.05), and laceration (0.02) also occurred at this test condition. Sensor fish data and results of model studies (release of neutrally buoyant beads in a physical model and CFD) also indicate that the worst hydraulic conditions existed for this condition (Richmond *et al.* 2003).

No overall consistent trend was observed for deep vs. shallow releases. In the fall, highest survival at Spillbay 2 was equally divided between deep and shallow releases; in Spillbay 4, deep and shallow survival values were nearly identical (1.0 deep, 0.99 shallow). In the spring, vertical release effects appeared to be spillbay and spill volume specific. At Spillbay 2, the survival of deep mid-bay released fish was virtually identical (1.0) to that of the shallow released fish (0.99) at 18 kcfs. However, at 21 kcfs the survival was lower for shallow released fish (0.95) than for deep released fish (0.98). At Spillbay 4 with a spill volume of 18 kcfs the survival of deep released fish was higher (1.0), though statistically non-significant, than for shallow released fish (0.97). Except for one estimate, the absence of a clear trend between survival and depth of release was also noted for injury and clean fish estimates. The notable exception was in the spring test at 21 kcfs at Spillbay 2 where the clean fish estimate for shallow, off-center released fish (0.95) was significantly ($P=0.10$) higher than the estimate for deep, off-center released (0.83) fish.

Passage through spillways can subject entrained fish to widely varying stilling basin hydraulic conditions and resulting survivability may be site-specific. Some of the site-specific characteristics include obstructions in the flow path, abrasive surfaces, magnitude of water cushion, spill pattern, spill volume, spillway configuration, pressure changes, and shear. As in the previous similar investigations at The Dalles Dam spillway, the actual path traversed by each alive balloon tagged fish released into each spillbay is unknown. Although data from concurrent release of "sensor fish" by Battelle Northwest Laboratory personnel to simulate the hydraulic conditions experienced by alive released fish are partially available at present to provide insights into the magnitude and duration of exposure to prevailing hydraulic conditions. When sensor fish data are complete, more detailed analysis of hydraulic conditions will be possible. Initial sensor fish data in Spillbay 2 and 4 indicated that only a few sensors seemed to be exposed for longer times than observed in earlier studies at Spillbays 9, 11, and 13. There was little evidence in the present study that many Spillbay 4 fish were retained and laterally transported across the stilling basin; and few fish appeared to be trapped in eddy areas. Minimization of lateral transport of fish may be attributed to the "water wall barrier" created by spill from adjacent spillbays to Spillbay 4. Model studies with physical and "water wall barriers" had indicated that a lateral transport across the stilling basin may be reduced by a training wall and thus enhancing egress of spillway entrained fish with a decreased level of potential injury/mortality. As entrainment duration increases, fish have an increased probability of collisions with hard objects and exposure to shear forces.

Survival is lower when a fish strikes a solid object, even at lower velocities, than when they enter standing water without obstructions. A variable mortality rate was observed by Bell *et al.* (1972) when fish struck a solid object at a velocity exceeding 20 fps. No fish injury was observed when fish impacted flowing water at a velocity of about 60 fps. They concluded that fish could be injured in any high-energy flow situation that creates momentarily localized sharp velocity changes. Based on field and laboratory tests on fish little to no injury (<1%) was observed on juvenile salmon subjected to entry velocities as high as 50 fps (PNNL *et al.* 2001). The estimated impact velocity of the discharge jet upon tailrace interception ranged from 66 to 68 fps during the fall 2002 investigation and 63 to 69 fps during the spring 2003 investigation at The Dalles Dam. The highest estimates of impact velocity in the spring (69 fps) was associated with the 21 kcfs spill volume for Spillbay 2 deep off-center releases. This condition produced the lowest survival and clean fish estimates observed in the spring experiment. It suggests that under certain hydraulic and specific fish release locations fish did collide with hard objects such as downstream baffle blocks. The highest incidence (7%) of injuries attributed to contact with hard objects occurred for deep released fish lined up with a baffle block (off-center) at 21 kcfs. CFD model and particle analysis (Richmond *et al.* 2003) indicate the potential injurious impact velocities at the baffle blocks, especially at 21 kcfs discharge for Spillbay 2. The modeling data supports the higher survival and clean fish estimates obtained in the present study in Spillbays 2 and 4 at 12 and 18 kcfs.

Although the spill conditions tested were not duplicated at both spillbays, results suggest that passage survival may not be assumed equal across all of the spillbays. At comparable spill patterns, fish survival was up to 2% higher at Spillbay 4 than at Spillbay 2 in the fall; however in the spring, survival was generally up to 2% higher at Spillbay 2 than at Spillbay 4. Similar differences in survival between spillbays were reported in earlier investigations (Normandeau Associates *et al.* 1996a, 2003). Survival was about 4% higher at Spillbay 4 than at Spillbays 3 and 6 in the fall 1995 investigations; in the 2002 spring investigation survival was about 4% higher at Spillbay 4 and 9 than at Spillbay 13.

Clean fish estimates also varied between spillbays and corroborated the trends in survival rates noted above. Fall clean fish estimates were up to 7% higher at Spillbay 4 than at Spillbay 2 at comparable discharges while spring estimates were mixed for both spillbays. In earlier investigations, (Normandeau Associates *et al.* 2003) clean fish estimates at Spillbays 4 and 9 were 1 to 3% higher than the estimates for Spillbays 11 or 13. These findings may have important implications when combined with detailed

fish distributions (vertically and laterally within and between spillbays) in predicting the impact on naturally entrained emigrants. There may be a need to evaluate fish passage survival and condition through multiple spillbays and patterns to determine the project spillway impacts on in-river migrants.

One of the objectives of the current study was to evaluate the effect of the “water wall barrier” on fish egress. Observations from previous studies at The Dalles Dam (Normandeau Associates and Mid Columbia Consulting 2001; Normandeau Associates *et al.* 2003) indicated that up to 25% of the tagged fish were carried into the south channel and nearby rock shelves. This was particularly evident for fish passed through Spillbays 9, 11, and 13. In the present investigation, few fish were carried towards the south channel and associated rock shelves; most released fish tended to remain in the dominant flow and little lateral transport was observed. The “water wall barrier” and spill pattern may have improved the fish egress pattern. These field observations corroborate the dye studies conducted at the USACE Vicksburg model.

Visual observations of the spill flow patterns, tailrace topography, and dispersal of post-passage tagged fish indicate that some spill patterns downstream of The Dalles Dam spillbay may be more conducive for fish predation losses, especially at warmer water temperatures. A combination of deep channels and adjacent rock shelf areas downstream of the spillway appears to provide ideal staging areas for predators. A large proportion of the project water carrying with it entrained juvenile salmonids passes through and over an extensive shallow rock shelf that lies across approximately two-thirds of the spill basin. The spill pattern during the spring test, along with the “water wall barrier” may explain the minimal predation levels (0.5%) observed.

5.0 CONCLUSIONS

Spill volume through a single spillbay of ≥ 12 kcfs along with spill from other spillbays and patterns enhanced survival and thus should be considered in future spill strategies; spill volume of > 18 kcfs and ≤ 9 kcfs appeared detrimental. The safe fish passage was maximized at spill volumes of 12 and 18 kcfs with a total spill of 112 to 108 kcfs. Data from sensor fish releases and results of CFD model and neutrally buoyant bead release experiments corroborate the above conclusions.

Fish released at deeper depth and off-center in Spillbay2 appeared to suffer greater injury rate, perhaps due to collisions with hard objects downstream of this spillbay. Although the range of estimated impact velocities was narrow (63 to 69 ft/s, spill jet into tailwater) the highest injury rate (11 %) coincided with the highest estimated impact velocity (69 ft/s); results of laboratory studied indicate fish suffer injury at impact velocity greater than 50 ft/s

Because only one spillbay (Spillbay 2) was tested with multiple release locations and spill volumes it is unknown whether these results are representative of other spillbays. To enhance certainty and confirm these results it is recommended that another spillbay be tested with a similar release scheme. The “water wall barrier” created at Spillbay 6 to simulate a physical barrier on the south side of Spillbay 4 with spill from adjacent spillbays in the May-June 2003 experiment appeared to minimize the lateral transport and retention of fish in the stilling basin. The “water wall barrier” appeared to improve fish egress out of the stilling basin.

1 Fish were released 10 ft above ogee (deep-mid and deep off-center) and 15 ft above ogee (shallow-mid and shallow off-center). Off-center releases were offset 8.5 ft from mid-spillbay.

Table 2-5

Required sample sizes (R) if control survival (S) is 0.99, 0.98, or 0.95, recapture rate (P_A) is 0.99, 0.98, or 0.95, and expected survival probability ($\hat{\tau}$) of treatment fish passed is 0.95, 0.97, and 0.99 to achieve a precision level (ϵ) of $\leq \pm 0.03$, 90% of the time. Highlighted values are discussed within the text.

Control Survival (S)	Expected Survival ($\hat{\tau}$)		
	0.95	0.97	0.99
<i>Recapture Rate=0.99</i>			
0.99	256	205	150
0.98	314	264	212
0.95	496	451	405
<i>Recapture Rate=0.98</i>			
0.99	314	264	218
0.98	373	325	274
0.95	556	514	469
<i>Recapture Rate=0.95</i>			
0.99	496	451	405
0.98	556	514	469
0.95	745	709	670

Table 2-6**Condition codes assigned to fish and dislodged balloon tags for fish passage survival evaluation.****FISH CODES**

- A** No visible marks on fish
- B** Flesh tear at tag site(s)
- C** Minor scale loss, 3 to 20% (%s for entire body in immediate recovery; for detailed injury examination %s are for section only)
- D** Major scale loss, >20% per side
- E** Laceration(s); tear(s) on body
- F** Severed body parts
- G** Hemorrhaging, bruised
- H** Stressed (lethargic, swimming poorly or sporadically)
- I** Spasmodic movement of body
- J** Very weak, barely gilling, died within 60 minutes of recovery
- K** Failed to enter system
- L** Fish likely preyed on based on telemetry, and/or circumstances relative to Turb'N recapture
- M** Substantial bleeding at tag site
- N** Bulging or missing eye(s)
- P** Observed predator attack or marks indicative of predator
- Q** Other information
- R** Replaced due to entrapment in unrecoverable locations (i.e., in rocks, gate slot; recovery time expired)
- T** Trapped inside tunnel/gate well
- V** Fins damaged (ripped, split, torn) or pulled from origin
- W** Abrasion/scrape
- X** No recovery information at all; fish remains unRecovered
- Z** Radio telemetry or other information; fish remains unRecovered

DISSECTION CODES

- B** Swim bladder ruptured or expanded
- D** Kidneys damaged (hemorrhaging)
- E** Broken bones obvious
- F** Hemorrhaging internally
- L** Organ displacement
- N** Heart damage, ruptured, hemorrhaging, etc.
- O** Liver damage, ruptured, hemorrhaging, etc.
- R** Necropsied, no obvious injuries
- S** Necropsied, internal injuries observed
- W** Head removed, i.e., otolith

TURB'N TAG CODES (not used in database)

- A** Fully inflated
- B** Partially inflated
- C** Pinhole, leaking
- D** Burst
- E** Not inflated at all

Table 3-1

Summary of tag-recapture data for juvenile chinook salmon passed through shallow and deep release locations¹ in Spillbays 2 and 4 and downstream of Spillbay 3 (control) under different spill conditions at low tailwater elevation, The Dalles Dam, October-November 2002. Test spill/total spill (kcfs) shown in parentheses. Proportions given in parentheses.

	Spillbay 2				
	(4.5/4.5)		(12/12*)		(12/72)

APPENDIX B

SUMMARY OF SURVIVAL RATES AT OTHER HYDROELECTRIC DAMS ON THE COLUMBIA RIVER BASIN

Appendix Table B-1

Sample size, recapture and control survival rates, and estimated 48 h survival (direct effects) of juvenile salmonids in passage through non-turbine exit routes at hydroelectric dams on the Columbia River Basin. Estimates based on balloon tag-recapture methodology (Heisey *et al.* 1992). Source: Normandeau Associates *et al.* (2003). Present study data are shown in italics.

Station	Exit Route	Species	Water	Sample Size	Head (ft)	Test Spill Volume (kcf)	Recapture Rates (%)		Control Survival (%)	Passage Survival (%)
			Temperature (°C)				Control	Treatment

APPENDIX C

INDIVIDUAL TRIAL DATA; FISH INJURY DATA; AND DAILY FISH DISPOSITION DATA

Appendix Table C-1

Daily tag-recapture data for juvenile chinook salmon passed through deep or shallow release locations¹ in Spillbays 2 and 4 and downstream of Spillbay 3 (control) under different spill conditions at low tailwater elevation at The Dalles Dam, October-November 2002. Injuries due to predation or unrecovered fish presumed ingested by a predator are shown in parentheses.

1 Fish released 10 ft (deep/mid-bay and deep/off-center) and 15 ft (shallow/mid-bay and shallow/off-center) above ogee. Off-center releases were offset 8.5 ft from mid-bay.

* Fish assigned dead in survival estimation.

Appendix Table C-3

Incidence of injury, scale loss, and temporary loss of equilibrium observed on treatment juvenile salmonids passed through Spillbays 2 and 4 and downstream of Spillbay 3 (control) under different spill conditions at low tailwater elevation, The Dalles Dam, October-November 2002.

1 Fish released mid-bay, 4 ft (deep) and 8 ft (shallow) above ogee.

2 Special test, Spillbay 2 only.

* Maladies attributed to predators and/or tags (e.g., tear at tag site).

Appendix Table C-5

Incidence of injury, scale loss, and temporary loss of equilibrium observed on treatment juvenile salmonids passed through shallow/deep and mid-bay/off-center release locations¹ in Spillbays 2 and 4 and downstream of Spillbay 3 (control) under four different spill conditions at high tailwater elevation, The Dalles Dam, May-June 2003.

1 Fish released 10 ft (deep/mid-bay and deep/off-center) and 15 ft (shallow/mid-bay and shallow/off-center) above ogee. Off-center releases were offset 8.5 ft from mid-bay.

* Maladies attributed to predators and/or tags (e.g., tear at tag site).

APPENDIX TABLE C-7

Short-term turbine passage survival data on individual chinook salmon released in Spillbays 2 and 4 at The Dalles Dam, October-November 2002. Fish were tagged with Normandeau's HI-Z Turb'N tags. Description of condition codes and details on injured fish are presented in Table 2-6.

APPENDIX D

DERIVATION OF PRECISION, SAMPLE SIZE, AND MAXIMUM LIKELIHOOD PARAMETERS, AND STATISTICAL OUTPUTS

DERIVATION OF PRECISION, SAMPLE SIZE, AND MAXIMUM LIKELIHOOD PARAMETERS

The statistical description below is excerpted from Normandeau Associates and Skalski (2000a). For the sake of brevity, references within the text have been removed. However, interested readers can look up these citations in the report prepared by Normandeau Associates and Skalski (2000a).

The estimation for the likelihood model parameters and sample size requirements discussed in the text are given herein. Additionally, the results of statistical analyses for evaluating homogeneity in recapture and survival probabilities, and in testing hypotheses of equality in parameter estimates under the simplified ($H_0: P_A = P_D$) versus the most generalized model ($H_A: P_A \neq P_D$) are given.

The following terms are defined for the equations and likelihood functions which follow:

R_C	=	Number of control fish released
R_T	=	Number of treatment fish released
R	=	$R_C=R_T$
n	=	Number of replicate estimates $\hat{\tau}_i$ ($i=1,\dots,n$)
a_C	=	Number of control fish recaptured alive
d_C	=	Number of control fish recaptured dead
a_T	=	Number of treatment fish recaptured alive
d_T	=	Number of treatment fish recaptured dead
S	=	Probability fish survive from the release point of the controls to recapture
P_A	=	Probability an alive fish is recaptured
P_D	=	Probability a dead fish is recaptured
τ	=	Probability a treatment fish survives to the point of the control releases (<i>i.e.</i> , passage survival)
$1-\tau$	=	Passage-related mortality.

The precision of the estimate was defined as:

$$P(-\varepsilon < \hat{\tau} - \tau < \varepsilon) = 1 - \alpha$$

or equivalently

$$P(-\varepsilon < |\hat{\tau} - \tau| < \varepsilon) = 1 - \alpha$$

where the absolute errors in estimation, *i.e.*, $|\hat{\tau} - \tau|$, is $<\varepsilon(1-\alpha)$ 100% of the time, $\hat{\tau}$ is the estimated passage survival, and ε is the half-width of a $(1-\alpha)$ 100% confidence interval for $\hat{\tau}$ or $1-\hat{\tau}$. A precision of $\pm 5\%$, 90% of the time is expressed as $P(|\hat{\tau} - \tau| < 0.05) = 0.90$.

Using the above precision definition and assuming normality of $\hat{\tau} - \tau$, the required total sample size (R) is as follows:

$$P\left(\frac{-\varepsilon}{\sqrt{Var(\hat{\tau})}} < Z < \frac{\varepsilon}{\sqrt{Var(\hat{\tau})}}\right) = 1 - \alpha$$

$$P\left(Z < \frac{-\varepsilon}{\sqrt{Var(\hat{\tau})}}\right) = \alpha/2$$

$$\Phi\left(\frac{-\varepsilon}{\sqrt{Var(\hat{\tau})}}\right) = \alpha/2$$

$$\frac{-\varepsilon}{\sqrt{Var(\hat{\tau})}} = Z_{\alpha/2}$$

$$Var(\hat{\tau}) = \frac{\varepsilon^2}{Z_{1-\frac{\alpha}{2}}^2}$$

$$\frac{\tau}{SP_A} \left[\frac{(1 - S\tau P_A)}{R_T} + \frac{(1 - SP_A)\tau}{R_C} \right] = \frac{\varepsilon^2}{Z_{1-\frac{\alpha}{2}}^2} .$$

where Z is a standard normal deviate satisfying the relationship $P(Z > Z_{1-\alpha/2}) = \alpha/2$, and Φ is the cumulative distribution function for a standard normal deviate.

If data can be pooled across trials and letting $R_C = R_T = R$, the sample size for each release is

$$R = \frac{\tau}{SP_A} [1 + \tau - 2S\tau P_A] \frac{Z_{1-\alpha/2}^2}{\varepsilon^2} .$$

By rearranging, this equation can be solved to predetermine the anticipated precision given the available number of fish for a study. In most previous investigations (Normandeau Associates and Skalski 2000a) this equation has been used to calculate sample sizes because of homogeneity between trials; in the present investigation sample size was predetermined using this equation.

If data cannot be pooled across trials the precision is based on

$$\sum_{i=1}^n (1 - \hat{\tau}_i) / n = 1 - \sum_{i=1}^n \hat{\tau}_i / n = 1 - \bar{\hat{\tau}} .$$

Precision is defined as

$$P(|\bar{\hat{\tau}} - \bar{\tau}| < \varepsilon) = 1 - \alpha$$

$$P(-\varepsilon < \bar{\hat{\tau}} - \bar{\tau} | < \varepsilon) = 1 - \alpha$$

$$P\left(\frac{-\varepsilon}{\sqrt{Var(\bar{\hat{\tau}})}} < t_{n-1} < \frac{\varepsilon}{\sqrt{Var(\bar{\hat{\tau}})}}\right) = 1 - \alpha$$

$$P\left(t_{n-1} < \frac{-\varepsilon}{\sqrt{Var(\bar{\tau})}}\right) = \alpha/2$$

$$\Phi\left(\frac{-\varepsilon}{Var(\bar{\tau})}\right) = \alpha/2$$

$$\frac{-\varepsilon}{\sqrt{Var(\bar{\tau})}} = t_{\alpha/2,n-1}$$

$$Var(\bar{\tau}) = \frac{\varepsilon^2}{t_{1-\alpha/2,n-1}^2}$$

$$\frac{\sigma_\tau^2 + \frac{\tau}{SP_A} \left[\frac{(1-S\tau P_A)}{R_T} + \frac{(1-SP_A)\tau}{R_C} \right]}{n} = \frac{\varepsilon^2}{t_{1-\alpha/2,n-1}^2}$$

where σ_τ^2 = natural variation in passage-related mortality.

Now letting $R_T=R_C$

$$\frac{\sigma_\tau^2 + \frac{\tau}{SP_A} \left[\frac{(1-S\tau P_A)}{R} + \frac{(1-SP_A)\tau}{R} \right]}{n} = \frac{\varepsilon^2}{t_{1-\alpha/2,n-1}^2}$$

which must be iteratively solved for n given R. Or R given n where

$$R = \frac{\frac{\tau}{SP_A} [(1-S\tau P_A) + (1-SP_A)\tau]}{\left[\frac{n\varepsilon^2}{t_{1-\alpha/2,n-1}^2} - \sigma_\tau^2 \right]}$$

$$R = \frac{\frac{\tau(1+\tau)}{SP_A}}{\left[\frac{n\varepsilon^2}{t_{1-\alpha/2,n-1}^2} - \sigma_\tau^2 \right]}$$

$$R = \frac{\tau(1+\tau)}{SP_A} \left[\frac{t_{1-\alpha/2,n-1}^2}{n\varepsilon^2 - \sigma_\tau^2 t_{1-\alpha/2,n-1}^2} \right].$$

The joint likelihood for the passage-related mortality is:

$$L(S, \tau, P_A, P_D | R_C, R_T, a_C, a_T, d_C, d_T) = \\ \binom{R_C}{a_C d_C} (SP_A)^{a_C} ((1-S)P_D)^{d_C} (1-SP_A - (1-S)P_D)^{R_C-a_C-d_C} \\ \times \binom{R_T}{a_T d_T} (S\tau P_A)^{a_T} ((1-S\tau)P_D)^{d_T} (1-S\tau P_A - (1-S\tau)P_D)^{R_T-a_T-d_T}.$$

The likelihood model is based on the following assumptions: (1) fate of each fish is independent, (2) the control and treatment fish come from the same population of inference and share that same survival probability, (3) all alive fish have the same probability, P_A , of recapture, (4) all dead fish have the same probability, P_D , of recapture, and (5) passage survival (τ) and survival (S) to the recapture point are conditionally independent. The likelihood model has four parameters (P_A , P_D , S , τ) and four minimum sufficient statistics (a_C , d_C , a_T , d_T).

Because any two treatment releases were made concurrently with a single shared control group we used the likelihood model which took into account dependencies within the study design (Normandeau Associates *et al.* 1995). For any two treatment groups (denoted T_1 and T_2), the likelihood model is as follows:

$$L(S, \tau_1, \tau_2, P_A, P_D | R_C, R_{T_1}, R_{T_2}, a_C, d_C, a_{T_1}, d_{T_1}, a_{T_2}, d_{T_2}) = \\ \binom{R_C}{a_C d_C} (SP_A)^{a_C} ((1-S)P_D)^{d_C} (1-SP_A - (1-S)P_D)^{R_C-a_C-d_C} \\ \times \binom{R_{T_1}}{a_{T_1} d_{T_1}} (S\tau_1 P_A)^{a_{T_1}} ((1-S\tau_1)P_D)^{d_{T_1}} (1-S\tau_1 P_A - (1-S\tau_1)P_D)^{R_{T_1}-a_{T_1}-d_{T_1}} \\ \times \binom{R_{T_2}}{a_{T_2} d_{T_2}} (S\tau_2 P_A)^{a_{T_2}} ((1-S\tau_2)P_D)^{d_{T_2}} (1-S\tau_2 P_A - (1-S\tau_2)P_D)^{R_{T_2}-a_{T_2}-d_{T_2}}.$$

This likelihood model has the same assumptions as stated in Normandeau Associates and Skalski (2000a) but has five estimable parameters (S , τ_1 , τ_2 , P_A , and P_D). The survival rate for treatment T_1 is estimated by τ_1 and for treatment T_2 , by τ_2 . A likelihood ratio test with 1 degree of freedom was used to test for equality in survival rates between treatments τ_1 and τ_2 based on the hypothesis $H_0: \tau_1 = \tau_2$ versus $H_a: \tau_1 \neq \tau_2$.

Likelihood models are based on the following assumptions: (a) the fate of each fish is independent; (b) the control and treatment fish come from the same population of inference and share the same natural survival probability, S ; (c) all alive fish have the same probability, P_A , of recapture; (d) all dead fish have the same probability, P_D , of recapture; and (e) passage survival (τ) and natural survival (S) to the recapture point are conditionally independent.

The estimators associated with the likelihood model are:

$$\hat{\tau} = \frac{a_T R_C}{R_T a_C}$$

$$\hat{S} = \frac{R_T d_C a_C - R_C d_T a_C}{R_C d_C a_T - R_C d_T a_C}$$

$$\hat{P}_A = \frac{d_C a_T - d_T a_C}{R_T d_C - R_C d_T}$$

$$\hat{P}_D = \frac{d_C a_T - d_T a_C}{R_C a_T - R_T a_C} .$$

The variance (Var) and standard error (SE) of the estimated passage mortality ($1 - \hat{\tau}$) or survival ($\hat{\tau}$) are:

$$Var(1 - \hat{\tau}) = Var(\hat{\tau}) = \frac{\tau}{SP_A} \left[\frac{(1 - S\tau P_A)}{R_T} + \frac{(1 - SP_A)\tau}{R_C} \right]$$

$$SE(1 - \hat{\tau}) = SE(\hat{\tau}) = \sqrt{Var(1 - \hat{\tau})} .$$

DERIVATION OF VARIANCE FOR WEIGHTED AVERAGE SURVIVAL ESTIMATE

The variance of a weighted average is estimated by the formula

$$\hat{\bar{\theta}}_w = \frac{\sum_{i=1}^n W_i \hat{\theta}_i}{\sum_{i=1}^n W_i}$$

with

$$\widehat{\text{Var}}\left(\hat{\bar{\theta}}_w\right) = \frac{\sum_{i=1}^n W_i \left(\hat{\theta}_i - \hat{\bar{\theta}}_w\right)^2}{(n-1) \sum_{i=1}^n W_i}$$

where $\hat{\bar{\theta}}_w$ = the weighted average,

$\hat{\theta}_i$ = the parameter estimate for the i th replicate,

W_i = weight.
